Random Forests™

Ensembles of bootstrapped, weakened trees

Terence Parr

https://www.stat.berkeley.edu/~breiman/randomforest2001.pdf

RF motivation

- Decision trees can often get training errors close to zero because we can grow very large trees to partition the feature space into tiny regions with 1 or just a few observations/samples; trees are very accurate on the training set and are not biased (no systematic under-prediction or systematic over-prediction)
- The downside is that decision trees overfit like mad; or, using stats nerd terminology, decision trees have high variance and don't generalize well
- High variance implies model parameters (tree structure) vary a lot if we tweak the training data just a little bit

How can we increases generality?

- Goal: keep the high accuracy, but increase the generality
- Recall: simplifying models can increase generality at cost of some error
- So, let's weaken our decision tree model but in a way that makes predictions noisy not biased
- That means the model's prediction might be too high for one test case and too low in another
 - But, the model will not always be too low or always too high, which would be biased
 - The expected value of weakened model's prediction is same as full strength model
- To compensate for the noise and claw back some accuracy, make an ensemble of such weakened trees: the ensemble is accurate on average
- Ensemble predictions are the aggregate of the trees' predictions (average prediction or majority vote)

The key trick is amnesia

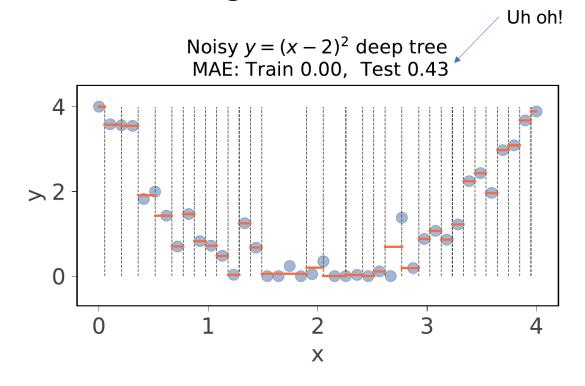

- Random forests are all about adding a bit of amnesia
- We will weaken trees by training each on a randomly selected subset of the training data: bagged trees
- Further, we will have training purposely forget about some features as we create decision nodes: random forests

Analogy: Crowdsourcing SF house prices

- Recruit multiple real estate agents to build house price models in their heads by visiting lots of houses; then each agent can estimate prices of unvisited houses
- Agents choose and examine house subsets independently
- There will be some overlap in visited houses sets but the subsets will be independent and identically distributed (i.i.d.)
- An agent trained on large house set is very accurate
- An agent trained on an i.i.d. subset is not biased but is less accurate—a prediction for one house might be too low but a prediction for another house might be too high (avoiding bias)
- The variance of the ensemble average will be much tighter than the variance of an individual tree's prediction
- Averaging all agents' predictions reduces noise and is unbiased

Ex: Overfit decision trees regressors

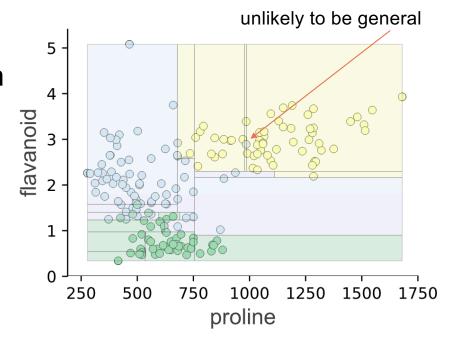

- Animation shows 1D feature space partitioning of i.i.d. sample sets
- Slightly different training data sets can yield very different decision trees
- Clearly the trees have gotten way too specific to the data set
- Notice how the training error is 0 but (20% hold out) test error is terrible!

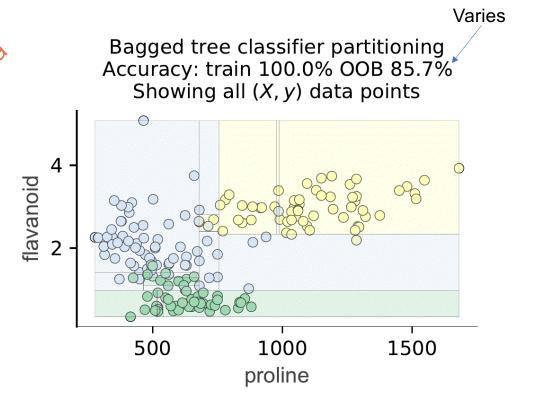

Ex: Overfit decision tree classifiers

- Here is a previous example where partitioning trapped a lonely blue in a sea of yellow
- In practice, we're given just one data set so let's do some sampling to get some i.i.d. "copies"
- Then see how different data sets give different partitioning (from different trees)

Partitioning from bootstrapped data

- Bootstrap (X, y) to simulate multiple i.i.d. data sets;
 each set gets ~63% of unique (X, y) data (sample n records with replacement)
- Animation shows 2D feature space partitions from various bootstraps
- Partitioning clearly varies a lot between bootstraps
- OOB == "out of bag" (more later)

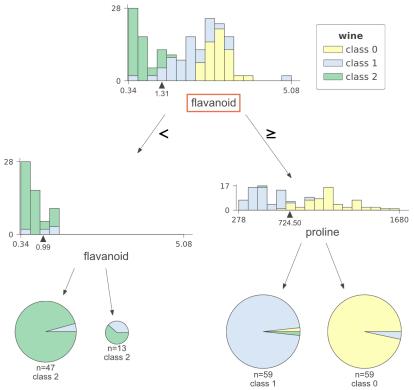

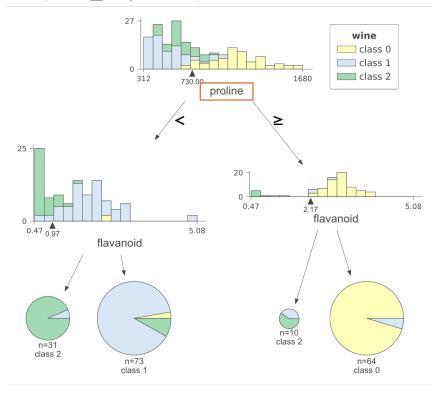

Uh oh!

Bootstrapping gives slightly different trees

DecisionTreeClassifier(max_depth=2)

Aside: Code for bootstrapping

NumPy

```
# Bootstrap: sample with replacement
n = len(y)
idx = np.random.randint(0,n,size=n)
X_train = X[idx]
y_train = y[idx]
```

```
# get OOB (out-of-bag) samples
mask = np.ones(n, dtype=bool)
mask[idx] = False
X_test = X[mask]
y_test = y[mask]
```

Pandas

```
# If data in dataframe
df = df.sample(len(df), replace=True)
```

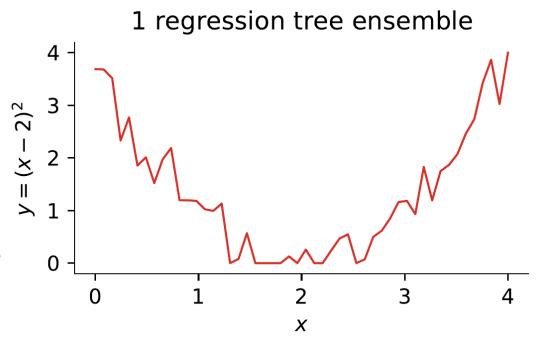

Bagged trees

Training trees on bootstrapped samples and aggregating predictions

Ensemble of high-variance regression trees

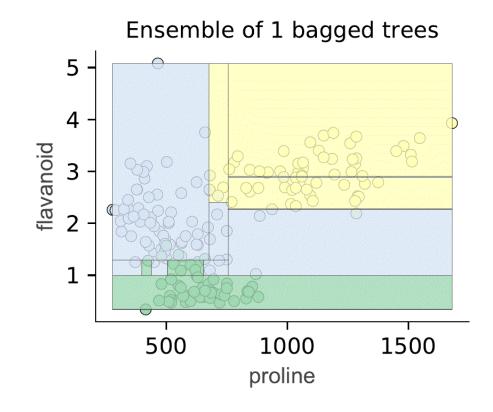

- Animation shows how averaging the prediction of an ensemble of overfit trees actually produces a reasonable combined prediction
- As we add trees, the average prediction (red line) smooths out to the underlying quadratic distribution from which we draw noisy samples
- Note: variance of individual tree predictions stays high as we add trees, but the variance of the ensemble average tightens (the magic of C.L.T.)

Ensemble of high-var. classification trees

- Animation shows overlapping prediction regions from multiple classifier trees
- Training data for each tree is bootstrapped from the original (X, y) data
- As we add trees, the averaged prediction regions become more stable and the decision boundaries more complex
- "Bag" is bootstrap aggregation

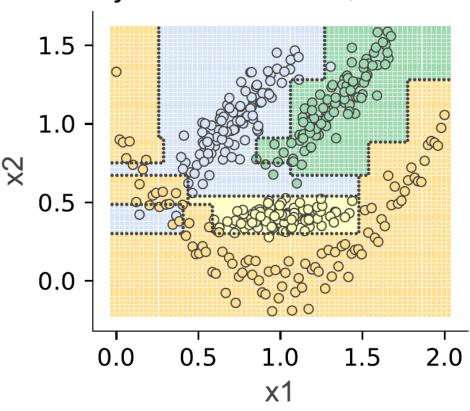

Ensemble classifier on synthetic data set

- Animation shows prediction regions from multiple bagged classifier trees
- Colored tiles indicate the probabilities of the various classes; e.g., yellow-orange color indicates uncertainty between those two classes
- Probability of class k at tile is proportion of trees that predict k

Synthetic dataset, 1 trees

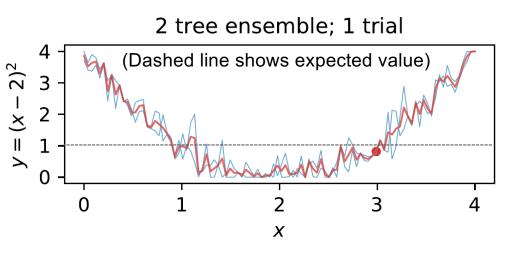

Animation uses experimental function I'm adding to dtreeviz

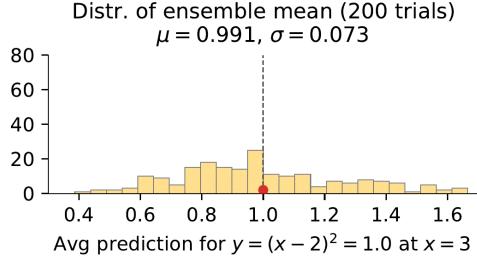

Ensemble's effect on bias and variance

- Train T trees on T i.i.d. X data sets
- Central limit theorem says that if variance of an i.i.d. random variable is σ^2 , the variance of the average of T such vars is σ^2/T
- So, as we add trees, the variance of the ensemble prediction will shrink, which means we squeeze out noise
- The average of the tree predictions is the same as the <u>expected</u> <u>prediction</u> from any tree trained on one of the *X* sets (since i.d.)
- Each tree gives noisy predictions, sometimes too low and sometimes too high, but is unbiased; so, ensemble is unbiased

Ex: variance of ensemble prediction

- Animation shows tree and ensemble predictions on left for T trees;
 magnitude of noise in blue tree predictions doesn't change with the number of trees but red line get less noisy with more trees
- At x = 3, expected value of ensemble is 1.0; create 200 separate ensembles of size T and compute variance of ensemble predictions at x = 3; distribution of ensemble average shown on the right

Problem: trees are not independent thinkers

- With real estate agent analogy, we implicitly assumed agents were independent thinkers, and not clones
- But, decision trees are like robot clones and, given the same bit of data, yield the same bit of tree
- Imagine worst case: bootstrapping yields *T* identical sets so ensemble gives exactly the same prediction as any single tree
- In practice, if there is one strongly predictive var out of p, then all trees would be similar; initial root splits, and many others, would likely be same

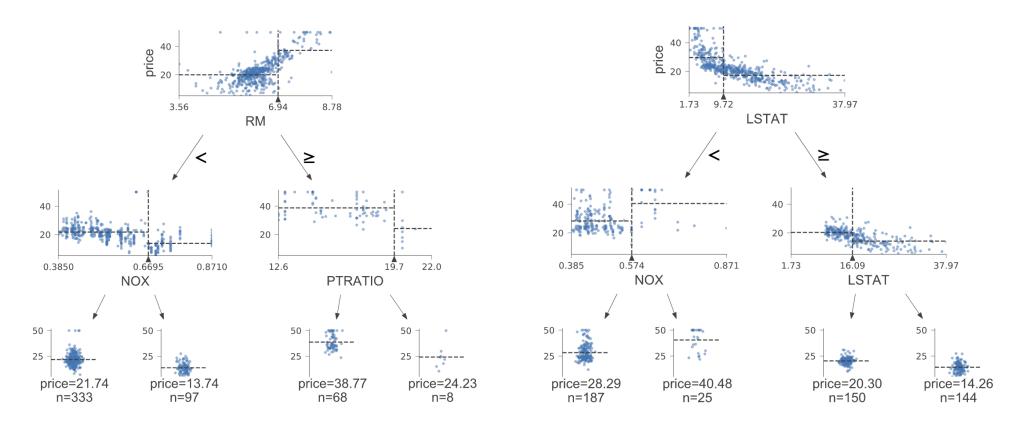

Random Forests

Ensembles of de-correlated bagged trees

Making trees independent thinkers

- Bagging overcomes most of the overfitting but we can improve generality a little by further weakening the trees in an effort to make them think more independently
- Restrict the available features when searching for a decision node split; choose from m randomly selected features (**amnesia** again!)
- Choose max features per split, $m \le p$, such as sqrt(p)
- Make sure chance of selecting predictive variables (m/p) is high enough to find predictor variables (See ESLII p596)
- Let validation error be your guide to choosing m
- A random forest is then just an ensemble of decision trees trained on bootstraps and whose feature selection strategy has a bit of amnesia

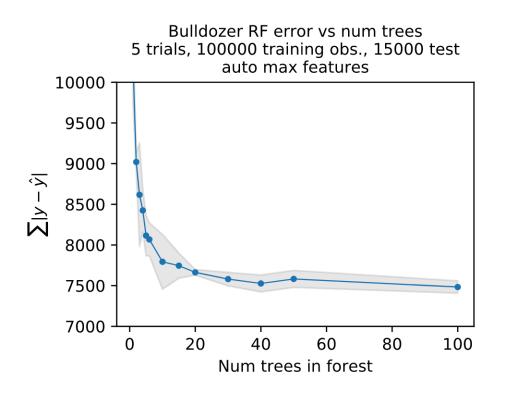

Ex: 2 trees trained on entire Boston set with m=5 (of 13)

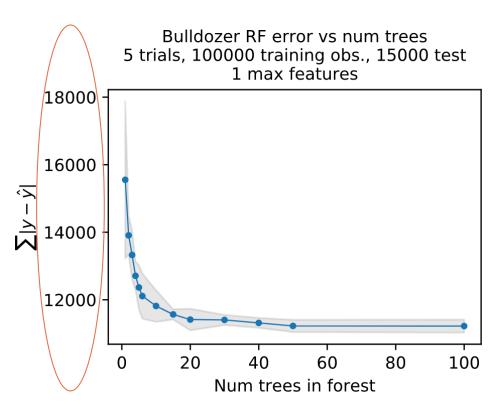

Choose from 5 randomly selected features during EACH split

If max_features too low, bad accuracy

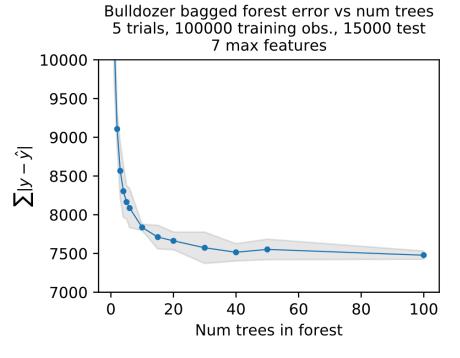

***** UNIVERSITY OF SAN FRANCISCO

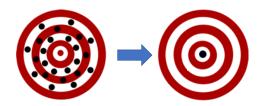

Effect of forest size on accuracy

- Why does accuracy improve greatly (initially) as we add trees?
 - Each tree sees only 2/3 of data so adding bootstrapped trees increases use of training data
- Why does accuracy asymptotically approach a minimum instead of continual improvement?
 - With enough trees, ensemble sees 100% of the training data; it's approaching the accuracy of single decision tree in ideal world

Properties (see Breiman 2001)

- p4 "Random forests do not overfit as more trees are added" Why?
 - Adding more trees actually REDUCES variance, and overfitting==variance
 - New trees get averaged in so each additional tree has less individual effect
 - New trees balance each other out, one might be too high, another too low
- p7 "It's relatively robust to y outliers and X noise" **Why**?
 - y outliers get shunted to their own leaf since doing so reducing loss function, particularly if squared-error is used
 - Noise vars aren't predictive so not chosen as split vars
- p10 Bagging helps more, the more unstable the model. Why?
 - Averaging is a smoothing operator, squeezing predictions to centroid
 - If model is low variance already, there is no point in bagging

Properties continued

- RFs are scale and range insensitive in features and target y Why?
 - Comparing feature values in decision nodes, not doing math on them
 - Computing mean or mode of y to predict
- ESLII p596 "Classifiers are less sensitive to variance [than regressors]" Why?
 - (not sure haha) I believe it has something to do with mode vs mean (mode is same until a threshold whereas mean is influenced by any value added, unless it is also the mean)

Bootstrapping vs subsampling

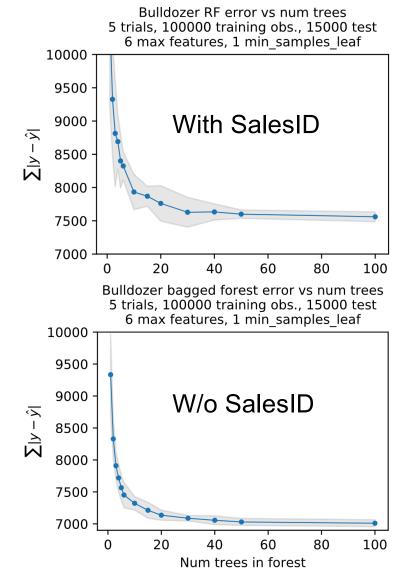

- Bootstrapping is sampling with replacement vs subsampling w/o replacement
- Friedman and Hall (2000): subsampling also works, showing that training trees with n/2 subsamples is similar in bias/variance to bagging http://statweb.stanford.edu/~jhf/ftp/bag.pdf
 - Smaller training set is a big win in terms of speed
 - Using even smaller fractions of n improve generality (reduce variance) because trees are less correlated (they work on different data chunks); note that each tree would become more biased as n subsample size decreases

RF Tuning strategy

- Good news: very little tuning needed
- Start with maybe 20 trees and work upwards til validation error stops getting better; or just pick 100
- Sklearn uses max_features= sqrt(p) by default; try dropping this to log(p), or similar; ESLII suggests p/3 for regression and sqrt(p) for classification
- Try adjusting min samples per leaf: 1, 3, 5, 10, 25, 100
- Goal: minimize validation error
- Can also try grid search, but I never bother;
 Start with num trees, then tune the others

Feature engineering beats model tuning

- SalesID: unique record ID, and is never seen again in future predictions
- Is that useful for prediction? No
- Does the model think it's useful? Yes
- Model is overfit not on noise but on falsely-predictive feature
 - Could be that sales ID correlates with inflation or change in type of models sold in auction creates "trend" in sale prices
- A case where using LESS data improves the model a lot (\$500 diff)
- Dropping useless features also often gives a small bump

Bagging summary

- Adding bagged trees does not increase bias; the avg of tree
 predictions is same as the expected prediction from any single
 bootstrapped tree (they are from same distribution: i.d.)
- Keep in mind, however, that a tree fit to bootstrapped data is only using 2/3 of the data and so each bagged tree will be less accurate than a single decision tree fit to entire data set
- Bagging does reduce variance, it is averaging predictions from lots of non-identical models afterall

• . . .

The RF algorithms

Fitting RFs

```
Algorithm: RFfit(X, y, loss, ntrees, max\_features, min\_samples\_leaf)

for i = 1..ntrees do

X', y' = bootstrap(X, y, size = |X|)

T_i = RFdtreefit(X', y', loss, max\_features, min\_samples\_leaf)

end
```

For regression, pass in loss = MSE or stddev For classifier, pass in loss = gini

Fitting a single tree in RF

Same as decision tree except we pass max_features to RFbestsplit()

```
Algorithm: RFdtreefit(X, y, loss, max\_features, min\_samples\_leaf)

if |X| \leq min\_samples\_leaf then return Leaf(y)

col, split = RFbestsplit(X, y, loss, max\_features)

if col = -1 then return Leaf(y)

lchild = RFdtreefit(X[X_{col} \leq split], y[X_{col} \leq split], ...)

rchild = RFdtreefit(X[X_{col} > split], y[X_{col} > split], ...)

return DecisionNode(col, split, lchild, rchild)
```

Finding best split in decision node in RF

```
Algorithm: RFbestsplit(X, y, loss, max\_features)
  best = (col = -1, split = -1, loss = loss(y))
                                                                         Only diff with decision tree
  vars = pick \ max_features \ variables \ from \ all \ p
  for col \in vars do
                                                                         Pick, say, 11 not all possible X
     candidates = randomly pick \ k \ll n \ values from \ X_{col}
                                                                         values. We get better generality
     foreach split \in candidates do
                                                                         and code is much faster!
       yl = y[X_{col} \leq split]
       yr = y[X_{col} > split]
       if |yl| < min\_samples\_leaf or |yr| < min\_samples\_leaf then continue
       l = \frac{|yl| \times loss(yl) + |yr| \times loss(yr)}{|y|}
                                           (weighted average of subregion losses)
       if l = 0 then return col, split
                                                                         Should pick midpoint between
       if l < best[loss] then best = (col, split, l)
                                                                         split value and next smallest X
     end
  end
  return best/col/, best/split/
                                                                                     TY OF SAN FRANCISCO
```

Simplest RF prediction (ESLII p588)

- But doesn't use all information to make best prediction
- Should use weighted averages / votes

Regression:
$$\hat{f}_{rf}^B(x) = \frac{1}{B} \sum_{b=1}^B T_b(x)$$
.

Classification: Let $\hat{C}_b(x)$ be the class prediction of the bth random-forest tree. Then $\hat{C}_{rf}^B(x) = majority\ vote\ \{\hat{C}_b(x)\}_1^B$.

RF prediction

Weighted average of y values among the leaves reached by running x down each tree

```
Algorithm: RFpredict_{regr}(\{T_1..T_{ntrees}\}, x)

Let leaves = \{leaf(T_t, x) \ \forall t = 1..ntrees\}

nobs = \sum_{t=1}^{ntrees} |leaves_t|

ysum = \sum_{t=1}^{ntrees} \sum_{y \in leaves_t} y

return \frac{1}{nobs} ysum Algorithm:
```

Count all y votes among the leaves reached by running x down each tree

```
Algorithm: RFpredict_{class}(\{T_1..T_{ntrees}\}, x)
counts[k] = 0 \ \forall \ classes \ k
foreach t = 1..ntrees do
leaf = leaf(T_t, x) \qquad (leaf \ reached \ by \ x)
foreach y \in leaf do
counts[y] += 1 \qquad (track \ count \ of \ leaf \ modes)
end
end
end
return argmax(counts)
```
